1 INTRODUCTION

The values of lengths in vacuum are comparable with each other. Because the speed of light in vacuum is constant, the distance of the object from the observation point increases with length. Usually, the length is measured in air is affected by the length in vacuum and the refractive index of air. A larger length measured in air indicates a larger length in vacuum or a smaller refractive index of air. Therefore, we cannot simply compare two lengths in air. Two approaches are used for length conversion to obtain the corresponding lengths in vacuum: one approach is based on precisely measuring the refractive index and the other is based on the application of the two-color method [1]. The former utilizes the relationship between the length in vacuum, the length in air, and the refractive index of air. The latter utilizes the relationship between the refractive indices of two different colors. The advantage of the two-color method is that the fluctuations caused by changes of the refractive index can be successfully avoided by using the measured length difference between the two colors.

During length conversion, the uncertainty of the refractive index measurement or the two-color method results in an uncertainty in the estimated value of the length in vacuum. The uncertainty of the calculated refractive index using the empirical formula [2]–[4] is well known. For example, the uncertainty of the Edlén empirical equations [2, 3] is on the order of 30–50 nm/m [5]. Although the two-color method has been studied by a number of researchers [6]–[12], the uncertainty of the length in vacuum obtained with this technique is not known. We do not know how the order of the uncertainty varies with the measurement environment. The difficulty in the associated uncertainty analysis lies in the fact that two refractive indices used in the two-color method are correlated.

By performing the length measurement using numerical simulations, one can evaluate the error of the two-color method without considering the correlation of two refractive indices. In the present study, we propose a generalized expression of the two-color method and estimate its error using numerical simulations.
The repetition interval length (APRIL) $\delta_{\text{vac}}$ can be used to realize the meter as follows [14]:

$$\gamma_{\text{vac}} = c_{\text{vac}} / f_p. \quad (2)$$

Here, $f_p$ is the frequency parameter (the frequency $f$ of the wavelength and the pulse repetition frequency $f_{\text{rep}}$ of the APRIL). In this part, the subscripts “vac” and “air” denote the values in vacuum and air, respectively.

The geometric distance $G$ is the true distance between two points in a vacuum. The distances measured using two different wavelengths ($\lambda_{\text{air},1}$ and $\lambda_{\text{air},2}$) or APRILs ($\delta_{\text{air},1}$ and $\delta_{\text{air},2}$) in air are the optical distances $L_{\text{air},1} = G/n_1$ and $L_{\text{air},2} = G/n_2$. $n$ represents the phase refractive index of air at the examined wavelength or the group refractive index of air $n_g$ of the APRIL. The estimate $L_{\text{est}}$ of this geometric distance can be obtained using the two-color method can be obtained as follows:

$$L_{\text{est}} = L_{\text{air},2} - A_\gamma \times (L_{\text{air},2} - L_{\text{air},1}), \quad (3)$$

where $\gamma$ denotes the measurement unit and $A_\gamma$ is the so-called $\Lambda$-factor defined as follows:

$$A_\gamma = [n(\gamma_{\text{vac},2}, T, P, H) - 1] / [n(\gamma_{\text{vac},2}, T, P, H) - n(\gamma_{\text{vac},1}, T, P, H)]. \quad (4)$$

Here, $T, P,$ and $H$ are the temperature, barometric pressure, and humidity, respectively.

By applying the law of propagation of uncertainty [15, 16] to Eq. (3), we have

$$u(L_{\text{est}})^2 = u(L_{\text{air},2})^2 + u(A_\gamma \times (L_{\text{air},2} - L_{\text{air},1}))^2. \quad (5)$$

Here, $u(x)$ denotes the uncertainty of variable $x$. The uncertainty of the first term of the right-hand side of Eq. (5) is

$$u(L_{\text{air},2})/L_{\text{air},2}^2 = [u(n_2)/n_2]^2. \quad (6)$$

The uncertainty of the second term of the right-hand side of Eq. (5) is

$$[u(A_\gamma \times (L_{\text{air},2} - L_{\text{air},1}))] / [A_\gamma \times (L_{\text{air},2} - L_{\text{air},1})]^2 = [u(A_\gamma)/A_\gamma]^2 + [u(L_{\text{air},2} - L_{\text{air},1}) / (L_{\text{air},2} - L_{\text{air},1})]^2. \quad (7)$$

Based on Eq. (4), the uncertainty of the first term of the right-hand side of Eq. (7) is

$$[u(A_\gamma)/A_\gamma]^2 = \left\{ u[n(\gamma_{\text{vac},2}, T, P, H) - 1] / n(\gamma_{\text{vac},2}, T, P, H) - 1 \right\}^2 + \left\{ u[n(\gamma_{\text{vac},2}, T, P, H) - n(\gamma_{\text{vac},1}, T, P, H)] / n(\gamma_{\text{vac},2}, T, P, H) - n(\gamma_{\text{vac},1}, T, P, H) \right\}^2 + \left\{ u[n(\gamma_{\text{vac},2}, T, P, H)] / n(\gamma_{\text{vac},2}, T, P, H) - 1 \right\}^2 \times \left\{ u[n(\gamma_{\text{vac},2}, T, P, H) - n(\gamma_{\text{vac},1}, T, P, H)] / n(\gamma_{\text{vac},2}, T, P, H) - n(\gamma_{\text{vac},1}, T, P, H) \right\}. \quad (8)$$

The uncertainty of the first term of the right-hand side of Eq. (8) is

$$[u[n(\gamma_{\text{vac},2}, T, P, H) - 1]]^2 = u[n(\gamma_{\text{vac},2}, T, P, H)]^2. \quad (9)$$

The uncertainty of the second term of the right-hand side of Eq. (8) is

$$\left\{ u[n(\gamma_{\text{vac},2}, T, P, H) - n(\gamma_{\text{vac},1}, T, P, H)] \right\}^2 = u[n(\gamma_{\text{vac},2}, T, P, H)]^2 + 2u[n(\gamma_{\text{vac},2}, T, P, H)] \times u[n(\gamma_{\text{vac},1}, T, P, H)] \times a(\gamma_{\text{vac},1}, \gamma_{\text{vac},2}, T, P, H). \quad (10)$$

In Eq. (10), $a(\gamma_{\text{vac},1}, \gamma_{\text{vac},2}, T, P, H)$ is the correlation coefficient used to characterize the degree of correlation between $u[n(\gamma_{\text{vac},2}, T, P, H)]$ and $u[n(\gamma_{\text{vac},1}, T, P, H)]$. $a(\gamma_{\text{vac},1}, \gamma_{\text{vac},2}, T, P, H)$ is defined as follows:

$$a(\gamma_{\text{vac},1}, \gamma_{\text{vac},2}, T, P, H) = u[n(\gamma_{\text{vac},2}, T, P, H)] \times u[n(\gamma_{\text{vac},2}, T, P, H)] / u[n(\gamma_{\text{vac},1}, T, P, H)]. \quad (11)$$

The uncertainty of the second term of the right-hand side of Eq. (7) is also the function of $u[n(\gamma_{\text{vac},2}, T, P, H)]$ and $u[n(\gamma_{\text{vac},1}, T, P, H)]$. That means its uncertainty is affected by the correlation coefficient $a(\gamma_{\text{vac},1}, \gamma_{\text{vac},2}, T, P, H)$. The estimation of the correlation coefficient $a(\gamma_{\text{vac},1}, \gamma_{\text{vac},2}, T, P, H)$ is difficult. In addition, as seen above, it is complicated to estimate the uncertainty of the two-color method based on the law of propagation of uncertainty. To solve this problem, by performing the numerical simulations, we evaluate the error of the two-color method without considering the correlation coefficient $a(\gamma_{\text{vac},1}, \gamma_{\text{vac},2}, T, P, H)$.

The calculation is performed as follows. First, we set a geometric length $G_{\text{set}}$. Then, we specify the environmental parameters $(T, P, H)$. Based on Eq. (3) and (4), we calculate a value $L_{\text{est}}$, which is estimated using the two-color method. Finally, we treat $L_{\text{est}} = G_{\text{set}}$ as the error of the two-color method.

**3 RESULTS AND DISCUSSION**

We abbreviate all instances of “wavelengths” or “center wavelengths of the APRILs” with “WLs” or “CWAs,” respectively.

The WLs and CWAs used in the calculations were 1560 nm and 780 nm, respectively. The value of $G_{\text{set}}$ was 1 m. The calculations were performed under standard environmental conditions (temperature of 20 °C, pressure of 101.325 kPa, and 0% humidity). The 0% humidity was selected based on previous studies [7–9, 11–21] that showed that the length $L_{\text{est}}$ can be determined with optimum precision when the humidity is 0%. To calculate $n_p$, we used the Edlén empirical equations, given in Ref. [5]. The calculation procedures for $n_q$ are described in Ref. [14]. The lengths obtained using different colors in a specific environment were calculated using $G_{\text{set}} / n$. Based on Eq. (3), using the calculated $L_{\text{air},1}, L_{\text{air},2},$ and $A_\gamma$ under
standard environment, we estimated the length in vacuum and considered the difference between the estimated length \( L_{\text{est}} \) and the set length \( G_{\text{set}} \) to be the error of two-color method \( u_{2\text{color}} \).

Figures 1 and 2 show the variation in \( u_{2\text{color}} \) when the environmental parameters change within realistic ranges \((T \in [10, 30] ^\circ\text{C}, P \in [80, 120] \text{kPa}, H = 0\%)\). As shown in Figure 1, \( u_{2\text{color}} \) is reduced with the increase of the temperature; however, it increases with the increase of air pressure, as shown in Figure 2.

Tables 1 and 2 display \( u_{2\text{color}} \) for both refractive indices under realistic environmental conditions \((T \in [10, 30] ^\circ\text{C}, P \in [80, 120] \text{kPa}, H = 0\% )\). The tables show that the minimum and maximum \( u_{2\text{color}} \) values are obtained for a temperature of 30°C and a pressure of 80 kPa, and a temperature of 10°C and a pressure of 120 kPa, respectively.

Note that \( u_{2\text{color}} \) is affected by the WLs or CWAs used. Hence, we examined the changes in \( u_{2\text{color}} \) by varying the WL or CWA. The range of WLs or CWAs used in the numerical simulations corresponds to the currently provided length standard in Japan, which is in the range of 500–1684 nm. Generally, the relationship between the WLs or CWAs in the two-color method is associated with a fundamental wave \( \lambda \) and its second harmonic \( \lambda /2 \). The WLs or CWAs of the fundamental wave were found to be in the range of 1000–1684 nm and those of the second harmonic wave were in the range of 500–842 nm. Figure 4 shows \( u_{2\text{color}} \) as a function of WL or CWA of the fundamental wave in vacuum. When the WL or CWA increased, \( u_{2\text{color}} \) decreased.

As can be seen in Figure 4, under standard environmental conditions, the minimum achievable \( u_{2\text{color}} \) corresponds to the 842 nm and 1684 nm pair. From Table 1, the minimum \( u_{2\text{color}} \) is obtained for 30°C and 80 kPa. In these conditions, \( u_{2\text{color}} \) of the 842 nm and 1684 nm pair was calculated as -42.2 nm/m using \( n_p \) and -43.1 nm/m using \( n_g \).

As can be seen in Figure 4, under standard environmental conditions, the maximum \( u_{2\text{color}} \) was obtained for the 500 nm and 1000 nm pair. According to Table 2, the maximum \( u_{2\text{color}} \) is obtained for 10°C and 120 kPa. In these conditions, \( u_{2\text{color}} \) was calculated as -111.1 nm/m for \( n_p \) and -117.6 nm/m for \( n_g \).

We can conclude that by using WLs or CWAs within the 500–1684 nm range under realistic environmental condi-
FIG. 3 Error of the two-color method $u_{\text{2color}}$ as a function of the length to be measured $G_{\text{set}}$.

FIG. 4 Error of the two-color method $u_{\text{2color}}$ as a function of WL or CWA in vacuum.

We also compare the two-color method and the techniques based on the Edlén empirical equations. The method using the empirical equations is a passive approach, because measuring environmental parameters is a passive activity. The two-color method can be used to make an interferometer less sensitive to environmental conditions by using two WLs or CWAs. Here, we show the change of $u_{\text{2color}}$ due to a change in environmental parameters. The results show the possibility of obtaining a smaller $u_{\text{2color}}$ by controlling the environmental parameters in laboratory conditions or selecting preferred conditions in open-air fields. Hence, the two-color method can be used as an active approach to compensate the influence of the refractive index of air. With further optimization, the two-color method can be used to obtain measurements with a smaller error than that of the empirical equations.

4 CONCLUSION

We proposed a generalized expression of the two-color method for length conversion, in which not only the wavelength but also the APRIL can be used as a scale. Using numerical simulations in a realistic environmental parameter range ($T \in [10, 30] ^{\circ}C, P \in [80, 120] $ kPa, $H = 0\%$), we found out for the first time that the achievable errors are in the range of -42.2 nm/m to -111.1 nm/m for $n_p$ and -43.1 nm/m to -117.6 nm/m for $n_g$ calculations. We also showed the change of the error with temperature, air pressure, and wavelength, which is useful to obtain the smallest error from an active point of view. The findings of this study provide a better insight into the two-color method, which will increase the opportunity to apply this method in various length-measurement applications.
